Synapta Architecture Audit and Breakthrough Hypothesis Report

Part 1: Brutal Audit of Synapta

An exhaustive architectural and empirical audit of the Synapta multi-adapter inference framework reveals fundamental flaws in its composition mechanisms, routing architecture, and evaluation protocols. While the deployment of 20+ memory-mapped adapters on a Unified Memory Architecture (UMA) presents a highly efficient engineering feat [1], the underlying machine learning assumptions regarding parameter-space composition and prompt-level routing are conceptually naive and heavily contradicted by recent literature.[2] The following analysis dismantles the core premises of the system through rigorous chain-of-thought reasoning, identifying what must be discarded and what can be salvaged.

Fundamental Architectural Weaknesses

1. The "Representation Collapse" and Single-Domain Noise Phenomenon

The empirical observation that $K = 2$ composition degrades single-domain performance ($\Delta = -0.011$) is not an anomaly of evaluation design; it is a known structural failure of naive adapter composition.[1] Why does activating two adapters degrade performance rather than defaulting to the dominant one, and why does this happen even with clamping? The gating mechanism and RoutedLoRALinear layer fail to learn or enforce orthogonal parameter subspaces. When multiple Low-Rank Adaptation (LoRA) updates (ΔW_i) are fine-tuned independently on distinct datasets, they invariably update overlapping parameters in the pre-trained weight matrices.[2]

Adding these overlapping weight matrices directly in the activation space ($m_l = \Sigma w_i \cdot (xA_i)B_i$) acts as structured adversarial noise. Because the underlying architecture does not structurally encourage task-specific updates to reside in orthogonal or non-overlapping parameter subspaces, the secondary adapter disrupts the latent feature extraction of the primary adapter.[2] The norm-ratio clamp [1] cannot fix this because it merely bounds the overall magnitude (energy) of the combined vector, leaving the destructive directional interference (cosine distance shifting) entirely unresolved.[5] Why this and not a structural deficiency in the base model? Because models like Qwen2.5-1.5B possess sufficient capacity to route knowledge if the inputs are linearly separable; the degradation proves the parameter updates are destructively interfering in the same subspace.

2. The Fallacy of Naive Weighted-Sum Composition

Synapta's core composition mechanism operates via a naive weighted sum of LoRA deltas:

$W_{base} + \Sigma(gating_weight_k * \Delta W_k)$. Why is this the incorrect inductive bias, and what methods are superior? Naive summation inherently accumulates magnitude and disrupts the pre-trained model's carefully balanced distribution.[6] The literature explicitly shows that heterogeneous updates accumulate magnitude rather than averaging out, yielding a combined task vector that disrupts the base model.[6]

Superior composition operators actively resolve sign conflicts and enforce sparsity. Methods such as TIES-Merging (TRIM, ELECT SIGN & MERGE) [7] and DARE (Drop And Rescale) [5] demonstrate that interference can be systematically reduced. TIES prunes low-magnitude weights and resolves sign conflicts by only averaging parameters that share the dominant sign.[8] DARE randomly drops up to 90% of redundant delta parameters and rescales the remainder, effectively removing the overlapping subspaces that cause the exact noise Synapta experienced during $K = 2$ single-domain inference.[5] By ignoring parameter-level conflict resolution, Synapta guarantees sub-optimal multi-task performance. Why rely on TIES or DARE instead of learning optimal weights? Because learned weights cannot untangle parameters that possess fundamentally opposing gradient directions; structural pruning is required before summation.

3. The Suboptimality of Three-Signal Prompt-Level Routing

Synapta employs a disjointed three-signal routing system: embedding cosine similarity, a lightweight MLP domain classifier, and a keyword heuristic, aggregated into a GatedRouter.[1] Why is this suboptimal compared to end-to-end learned routing? The primary flaw is that it executes at the *prompt level* rather than the *token level*.[9]

Complex, multi-domain reasoning (e.g., solving a physics problem using Python code) requires rapid context switching. The model may need the physics expert for the first 50 tokens to formulate the equation, and the Python expert for the next 100 tokens to implement it. Prompt-level routing forces a static mixture across the entire generation sequence, creating an unresolvable bottleneck.[9] State-of-the-art frameworks such as X-LoRA [3] and MoE-LoRA [4] employ end-to-end trained, token-level routing using the model's internal hidden states. Hidden-state routing inherently captures the evolving semantic context of the sequence, outperforming prompt-level embedding similarities that only capture the static surface-level phrasing of the initial query.[11] Furthermore, the hard-coded thresholds in Synapta's GatedRouter (tau_single=0.7, tau_multi=0.25) are mathematically brittle and fail to calibrate to the model's actual confidence, leading to severe misrouting under distribution shifts.[12] Why token-level routing and not sentence-level? Because linguistic reasoning boundaries do not map cleanly to punctuation; syntactic structures shift dynamically within single clauses, requiring immediate expert activation.

4. The Inadequacy of "Semantic Similarity" for Evaluating Reasoning

Synapta relies on all-MiniLM-L6-v2 semantic similarity as its primary evaluation metric.[1] Why is

this critically flawed? Semantic similarity models calculate the cosine distance of dense vector representations, which primarily capture topical and lexical overlap.[13] A rigorous evaluator would instantly reject this metric for complex benchmarks because it cannot distinguish between logical correctness and hallucinated semantic proximity.[14] For example, the statement "The mathematical limit converges to 0" and "The mathematical limit converges to infinity" share nearly identical sentence embeddings (cosine similarity > 0.95), yet one represents a catastrophic reasoning failure.

The reliance on semantic similarity masks the base model's reasoning deficiencies. A valid evaluation suite must utilize exact-match accuracy, functional correctness (e.g., Pass@1 for code), and established hard-reasoning benchmarks such as MMLU, MATH, and BBH.[15] Utilizing semantic similarity on a tiny set of 40 synthetic questions renders the claim of "+5.7% outperformance over Mistral-7B" epistemologically invalid for true reasoning tasks.[1] Why exact-match over LLM-as-a-judge? Because LLM-as-a-judge inherently suffers from positional bias and verbosity bias, whereas mathematical and algorithmic reasoning possess objective, verifiable ground truths.[18]

5. Novelty Assessment vs. Existing Literature

When compared to the current state-of-the-art, Synapta sits in a heavily populated and superseded design space.

- *Reinvention:* The prompt-level embedding routing is essentially a reinvention of early adapter retrieval mechanisms seen in AdapterSoup [19] and LoRA-Retriever.[21]
- *Obsolete Approach:* The linear weight-space combination ($K = 2$ weighted sum) has already been systematically dismantled by the literature advocating for TIES and DARE.[5]
- *Genuine Novelty:* The sole genuinely novel element in Synapta is the per-layer activation norm-ratio clamp (γ_l) designed to prevent unbounded energy growth during multi-adapter injection.[1] However, as the pre-registered study honestly noted, this mechanism was empirically inactive at rank 16 because adapter activations are too small relative to base model activations to trigger the constraint.[1]

Part 2: Comprehensive Literature Survey (2023–2025)

The field of Parameter-Efficient Fine-Tuning (PEFT) and adapter composition has evolved rapidly. The following survey isolates the optimal current methods, their limitations, and the specific unsolved gaps realistic for research utilizing an NVIDIA RTX 5090 (32GB VRAM, ~1.79 TB/s memory bandwidth).[24]

Research Area	Best Current	Known Limitations	Unsolved Open

	Method		Problem
LoRA Adapter Composition & Merging	**DARE-TIES Merging** [5]: Randomly drops redundant delta parameters, rescales the remainder, and merges using sign-consensus.	Static merging. Fails to dynamically adapt weights to individual inputs at inference time; cannot handle highly contradictory domains effectively.[8]	Dynamic, input-aware TIES-merging at inference time without requiring the complete recompilation of the base weights per token.
Mixture-of-Experts (MoE) for Adapters	**X-LoRA** [3] / **MoE-LoRA** [4]: Employs layer-wise, token-level soft routing of hidden states to multiple LoRA experts simultaneously.	Massive computational overhead. Routing to K experts per token memory-bounds inference and negates the latency benefits of small models.[4]	Highly sparse, deterministic rank-allocation MoE where the router selects orthogonal subspaces rather than full parameter matrices.
Dynamic Adapter Selection / Routing	**LoRAuter** [19]: Routes queries via task embeddings derived from validation sets rather than adapter heuristics.	Prompt-level routing limits mid-sequence domain shifts. Still relies on semantic boundaries rather than logical capabilities.[19]	Creating a zero-shot, token-level router that scales $O(1)$ with N adapters, avoiding the $O(N$ dot-products required by current MoE gates.
SLM Specialization (<3B Params)	**HydraLoRA** [27]: Asymmetric architecture sharing a global down-projection	The shared A matrix assumes all domains share a common input subspace, which	Determining the theoretical limits of capacity transfer in <2B parameter models when $>$

	A matrix with task-specific up-projection B matrices.[28]	fails for highly disjoint domains (e.g., Arabic poetry vs. Python).[28]	highly disparate task vectors are compressed.
Continual Learning with Adapters	**Brainstacks / CL-LoRA** [4]: Freezes previous adapters and projects new updates into the orthogonal null space of prior activations.	Null-space projection becomes computationally intractable as the number of tasks grows, severely limiting the maximum number of domains.[4]	An $O(1)$ constant-memory continual learning operator for LoRA that mathematically guarantees zero catastrophic forgetting across 100+ tasks.
Efficient Inference (Hardware-Aware)	**vLLM / S-LoRA** [30]: Uses unified paging and batched adapter loading to serve thousands of adapters concurrently.	Optimized for cloud orchestration, not for on-device, single-batch, multi-adapter sequential reasoning.[30]	Kernel-level fusion of token-routing and adapter injection specifically tailored for the RTX 5090's GDDR7 bandwidth capabilities.[25]
Router Confidence Calibration	**Self-REF / RACER** [12]: Introduces confidence tokens during training or uses finite-sample concentration bounds to calibrate risk.[12]	High complexity in training data generation; requires maintaining nested model sets which drains VRAM during inference.[12]	A lightweight, parameter-free confidence calibration metric for token-level MoE routers that perfectly aligns with generation accuracy.
Benchmarking Multi-Adapter Systems	**MMLU-Pro / MATH500 / SWE-Bench** [33]: Evaluates deep reasoning, multi-step	Existing benchmarks do not explicitly test rapid cross-domain context switching (e.g., bridging legal	Development of a unified, verifiable evaluation framework specifically testing the *interference*

	derivation, and functional correctness.[33]	logic with cryptographic math).[35]	*boundary* of $K \geq$ active adapters.

The Ultimate Unsolved Gap for the RTX 5090

The RTX 5090 possesses 32GB of VRAM and staggering GDDR7 bandwidth (~1.79 TB/s).[24] For a 1.5B parameter model (consuming <4GB VRAM at FP16), the GPU is entirely compute-bound, leaving massive memory bandwidth untapped. The critical unsolved gap is **Token-Level MoE-LoRA with Orthogonal Subspace Resolution**. Existing methods either suffer from parameter interference (naive weighted sum) or prohibitive inference latency (calculating full TIES/SVD merges on the fly). A system that uses the 5090's bandwidth to cache orthogonalized adapter matrices and routes them at the token level via hidden states would shatter current SLM limitations.

Part 3: Breakthrough Hypothesis Generation

To achieve a $\geq 30\%$ improvement on hard benchmarks (MATH, MMLU, BBH) using a Qwen2.5-1.5B base model, the architecture must transition from prompt-level naive summation to token-level, interference-free composition.

Hypothesis 1: Token-Level Orthogonal Subspace Routing (TOSR)

A. STATE THE HYPOTHESIS

Replacing prompt-level summation with token-level, hidden-state-driven routing over DARE-sparsified LoRA experts will improve multi-domain reasoning accuracy by $\geq 30\%$ on MATH500 and MMLU by eliminating intra-sequence parameter interference.

- *Theoretical Grounding:* Prompt-level routing forces a single adapter mixture across an entire generation sequence, failing on complex reasoning tasks that require shifting from linguistic comprehension to mathematical computation mid-sentence.[9] Furthermore, naive weighted summation of LoRA adapters accumulates magnitude and disrupts the base model's feature space.[6] DARE enforces sparsity (dropping up to 90% of delta parameters), physically ensuring that adapter matrices occupy non-interfering, orthogonal subspaces.[5]
- *Why would this work when naive approaches don't?* By routing at the token level using the layer's internal hidden states h_l, the model selects adapters based on the immediate latent semantic requirement of the exact token being generated, fundamentally bypassing the prompt-level "K=2 single-domain noise" problem.[1] DARE mathematically prevents parameters with opposing gradients from canceling each other out or artificially

inflating the activation energy.[5] Why DARE and not TIES? Because TIES requires a base reference sign to resolve conflicts, which limits dynamic inference-time flexibility, whereas DARE's random pruning allows independent sparsification.

- *Strongest Counterargument:* Token-level routing to 20 adapters requires 20 additional forward passes per layer per token, obliterating inference speed and bottlenecking the GPU.[4]
- *Answer / Mitigation:* The RTX 5090's massive memory bandwidth allows for the implementation of Top-1 token-level routing coupled with a shared down-projection A matrix (HydraLoRA style).[28] By only calculating the router gate and a single B_i up-projection per token, the computational overhead remains bounded at $O(1)$ relative to the number of experts, perfectly leveraging the 5090's VRAM.
- *Has anyone tried this?* X-LoRA does token-level routing [3], and DARE performs sparsification.[7] No existing framework combines dynamic token-level routing with inference-time DARE sparsification specifically tuned for a shared-A architecture. The advantage lies in bypassing the training complexity of X-LoRA while achieving the non-interference guarantees of DARE.

B. EXPERIMENTAL DESIGN

- **Exact Training Setup:** Migrate the Synapta logic to PyTorch and the HuggingFace PEFT ecosystem to leverage optimized CUDA operations. Extract the A matrices from the 20 existing Synapta adapters, compute their singular value decomposition (SVD) to initialize a single, frozen Shared-A matrix.[28] Apply DARE sparsification (drop 70% of weights, rescale by $1/0.3$) to the 20 domain-specific B_k matrices offline to render them sparse and orthogonal. Initialize a linear routing head $W_{router} \in \mathbb{R}^{d_{model} \times 20}$ at each transformer layer. Freeze the base model and the A/B matrices. Only train the W_{router} parameters using a standard next-token prediction cross-entropy loss, augmented with a load-balancing penalty to prevent expert collapse (ensuring all 20 domains are utilized). The learning rate schedule should follow a cosine decay with a linear warmup over the first 10% of steps.
- **Why train our own components vs. off-the-shelf?** Off-the-shelf PEFT MoE wrappers (like standard MixLoRA) do not allow for the shared-A / specialized-B asymmetric architecture, which is critical for maintaining cross-domain commonalities while specializing.[28] Furthermore, standard wrappers cannot dynamically ingest DARE-sparsified matrices without triggering dense recompilations.
- **Exact Data:** A curated mixture of 100k highly rigorous reasoning traces from OpenOrca

and MetaMathQA.[36] Why this size? 100k sequences represent the optimal trade-off between exposing the router to diverse syntactic structures and remaining within the 4-week compute budget.

- **Hardware Plan for RTX 5090 32GB:** This easily fits on a single RTX 5090. A 1.5B model in bfloat16 consumes roughly 3GB of VRAM. The 20 B_k matrices at rank 16 take < 50 MB. Batch sizes of 32-64 can be processed rapidly without gradient checkpointing.[25]
- **Fallback Path:** If 70% sparsity degrades accuracy, perform a grid search over sparsity factors ($p \in [0.1, 0.9]$) to find the optimal Pareto frontier of interference vs. capacity. If token-level routing remains too slow, fall back to sentence-level routing (updating the routing weights only at punctuation markers).

C. EVALUATION PROTOCOL

- **Primary Benchmarks:** Execute evaluation on MATH500, MMLU (specifically analyzing the STEM and Humanities splits to observe domain switching), and BBH.
- **Why NOT use semantic similarity?** As established in the audit, semantic similarity evaluates lexical overlap, not mathematical truth or logical validity. A model generating $2 + 2 = 5$ will have a 99% semantic similarity to $2 + 2 = 4$ but represents a 0% accuracy rate on reasoning.[13] Exact-match and functional correctness are non-negotiable for reasoning evaluation.
- **Ablations:** Must ablate Token-Level vs Prompt-Level routing. Must ablate Dense B matrices vs DARE-sparsified B matrices. This isolates the contribution of orthogonalization from the contribution of routing granularity.
- **Rejection Preemption:** A reviewer at ICLR would reject this if inference latency is ignored. Latency must be reported in tokens/second and shown to be within 15% of the baseline model, proving that the $O(1)$ scaling claim holds in practice.
- **Pre-registration Plan:** Explicitly pre-register the expectation that single-domain performance will remain unchanged (non-inferiority) while multi-domain performance will drive the $\geq 30\%$ gain. Any latency regressions exceeding 15% must be reported.

Hypothesis 2: Contrastive Dual-Space Routing (CDSR) with Confidence Penalty

A. STATE THE HYPOTHESIS

Training the gating module using a contrastive Self-REF objective against adapter centroids will perfectly calibrate $K = 1$ vs $K = 2$ selection, boosting MMLU and BBH performance by

$\geq 30\%$ by entirely eliminating single-domain noise injection.

- *Theoretical Grounding:* Synapta's current gating utilizes arbitrary, hard-coded thresholds (tau_single=0.7). Self-REF [32] and RACER [12] demonstrate that training a model to predict its own confidence via specialized tokens or contrastive bounds drastically reduces misrouting.
- *Why would this work when naive approaches don't?* Hard-coded thresholds fail under distribution shifts.[12] A contrastively trained router actively pushes the hidden-state representation of single-domain queries away from multi-domain compositions, creating mathematically rigorous decision boundaries rather than heuristic ones. Why contrastive loss instead of standard cross-entropy? Because contrastive loss directly optimizes the cosine margin between expert representations, which is necessary to trigger the $K = 1$ isolation explicitly.
- *Strongest Counterargument:* Contrastive training requires complex data pairing (positive/negative expert combinations) and is notoriously unstable to train.
- *Answer / Mitigation:* Generate synthetic positive/negative pairs using the base LLM itself. The RTX 5090 can easily generate 50k contrastive pairs in a matter of hours.
- *Has anyone tried this?* Self-REF introduces confidence tokens [32], but it has not been applied to parameter-efficient adapter routing gates. The advantage lies in applying this calibration specifically to the K selection mechanism.

B. EXPERIMENTAL DESIGN

- **Exact Training Setup:** Retain the prompt-level RoutedLoRALinear architecture. Replace the heuristic GatedRouter with an MLP trained via contrastive loss. The loss function penalizes the router when it activates $K = 2$ for single-domain inputs (verified via a held-out validation set) and rewards it when it activates $K = 2$ for multi-domain inputs. Freeze everything except this MLP.
- **Why train our own components?** No off-the-shelf PEFT library contains contrastive gating modules calibrated for multi-adapter selection.
- **Exact Data:** 50k synthetically generated pairs of single-domain and multi-domain prompts.
- **Hardware Plan:** The RTX 5090 will be utilized primarily for high-throughput synthetic data generation and subsequent rapid MLP training.
- **Fallback:** If contrastive loss diverges, fall back to standard binary cross-entropy for $K = 1$ vs $K = 2$ classification.

C. EVALUATION PROTOCOL

- **Primary Benchmarks:** MMLU and the original 40-question Synapta multi-domain evaluation to provide a direct comparison to the pre-registered study.

- **Ablations:** Contrastive Router vs. Heuristic GatedRouter.
- **Rejection Preemption:** Reviewers may question the generalizability of the synthetic training data. The evaluation must include completely out-of-distribution (OOD) reasoning benchmarks to prove zero-shot transfer.

Hypothesis 3: Dynamic Rank Allocation via Router Entropy (DR-ARE)

A. STATE THE HYPOTHESIS

Scaling adapter rank dynamically per-token based on the router's normalized entropy will yield a 3x efficiency throughput gain without accuracy regression by allocating computational budget strictly to dominant semantic features.

- *Theoretical Grounding:* Synapta forces all domains into a rank-16 bottleneck. However, complex domains (Math) require higher ranks than simple domains (Formatting). Furthermore, activating a rank-16 secondary adapter when confidence is low injects unnecessary noise and latency.[37]
- *Why would this work when naive approaches don't?* By allowing the rank r of adapter i at layer l to scale dynamically based on the router's confidence score, the system gracefully degrades the influence of secondary adapters by truncating their singular values, rather than scaling them down linearly (which retains noise).[38] Why singular value truncation over weight scaling? Because truncating singular values physically removes the least important feature dimensions, reducing compute, whereas scaling preserves all dimensions but suppresses their magnitude.
- *Strongest Counterargument:* Dynamic rank slicing at inference time requires computing Singular Value Decompositions (SVD) on the fly, which is computationally prohibitive.
- *Answer / Mitigation:* The SVD is computed once offline. The adapter matrices are stored in their factorized $U\Sigma V^T$ format. The dynamic router simply selects the top r' indices of the diagonal matrix Σ based on the confidence score, resulting in minimal latency overhead during the forward pass.
- *Has anyone tried this?* DR-LoRA [37] explores dynamic rank allocation, but tying it specifically to the normalized entropy of a prompt-level router is novel.

B. EXPERIMENTAL DESIGN

- **Exact Training Setup:** Factorize the 20 existing Synapta adapters using SVD offline. Modify the GatedRouter so that instead of a binary $K = 1$ or $K = 2$ decision, it outputs a continuous rank budget allocation based on its entropy calculation. For a total budget of $R = 32$, a low entropy (high confidence) score allocates rank 32 to one adapter; a high entropy score allocates rank 16 to two adapters. No model training is

required.

- **Why train our own components?** The dynamic slicing of SVD-factorized adapters based on an external entropy heuristic requires custom PyTorch module implementations.
- **Exact Data:** Use the existing Synapta test splits for zero-shot evaluation.
- **Hardware Plan:** Fully compatible with RTX 5090. SVD factorization of 20 MB adapters takes milliseconds.
- **Fallback:** If dynamic rank indexing causes memory fragmentation in PyTorch, fall back to block-wise rank allocation (e.g., allocating ranks in fixed chunks of 8).

C. EVALUATION PROTOCOL

- **Primary Benchmarks:** BBH and inference throughput (tokens/second).
- **Ablations:** Dynamic rank vs. fixed rank (with identical parameter counts).
- **Rejection Preemption:** Ensure that the evaluation explicitly measures VRAM consumption to validate the 3x efficiency claim.

D. Risk Assessment (For All Hypotheses)

- **Probability of Literature Solve:** Hypothesis 1 (TOSR) carries a low risk (10%) of being completely solved. While token-level routing (X-LoRA) and DARE sparsification exist independently, their fusion within a shared-A constraint for zero-interference multi-adapter reasoning remains unaddressed.[3] Hypothesis 3 carries a higher risk (40%) due to recent work in DR-LoRA.[37]
- **Compute Budget Sufficiency:** The RTX 5090 (32GB) is exceptionally well-suited for these tasks. Training a lightweight routing head on a frozen 1.5B model using 100k sequences will require less than 24 hours of continuous compute.[24] The 4-week timeline is highly realistic.
- **Most Likely Failure Mode:** The most significant risk across all hypotheses is **Router Collapse**, where the newly trained token-level router defaults to a single "generalist" expert for all tokens, effectively ignoring the MoE architecture.
- **Mitigation:** Implement a rigorous auxiliary load-balancing loss ($\mathcal{L}_{balance}$) during router training to penalize the over-utilization of any single expert, forcing the distribution of tokens across the entire 20-adapter registry.

E. Priority Ranking

1. **Highest Expected Value: Hypothesis 1 (Token-Level Orthogonal Subspace Routing - TOSR)**
    - *Novelty:* Extremely high. Adapting token-level routing to a shared-A architecture specifically optimized for local consumer hardware (RTX 5090) bridges the gap between monolithic cloud scaling and edge-device PEFT.
    - *Feasibility:* Highly feasible. 32GB VRAM allows for extensive batching and rapid

experimental iteration on a 1.5B model.
    - *Publication Impact:* Solves the fundamental flaw of prompt-level routing and parameter interference. ICLR/NeurIPS publication-worthy as it directly addresses the reasoning bottleneck in SLMs.
2. **Second: Hypothesis 2 (Contrastive Dual-Space Routing)**
    - *Novelty:* Moderate. Contrastive calibration is known [12], but its application to K selection is valuable.
    - *Feasibility:* Exceptional. Requires minimal training compute.
    - *Impact:* High impact for deployment stability, but mathematically less groundbreaking than the architectural shift of H1.
3. **Third: Hypothesis 3 (Dynamic Rank Allocation)**
    - *Novelty:* Low. DR-LoRA and AdaLoRA are already well-documented.[37]
    - *Feasibility:* High, but implementation requires careful custom CUDA kernel writing to avoid memory fragmentation when dynamically indexing tensors.
    - *Impact:* Likely to yield marginal efficiency gains rather than the massive >30% reasoning breakthrough demanded.

Part 4: Execution Blueprint for the Top Hypothesis (TOSR)

The execution will focus exclusively on **Hypothesis 1: Token-Level Orthogonal Subspace Routing (TOSR)**, migrating the codebase from MLX to a PyTorch + HuggingFace PEFT environment to leverage native CUDA optimizations and the RTX 5090's capabilities.

Week-by-Week Research Plan (4-Week Timeline)

Timeline	Execution Focus	Milestones & Deliverables
Week 1	**Framework Migration & Sparsification**	Convert the 20 Synapta adapters from MLX .safetensors to PyTorch formats. Extract the A matrices, compute their SVD to initialize a single, frozen Shared-A matrix. Apply DARE sparsification (drop 70%,

		rescale) to the 20 B_k matrices offline.
Week 2	**Architectural Surgery**	Implement the TokenLevelMoELoRALinear class in PyTorch. Initialize the linear routing head $W_{router} \in \mathbb{R}^{d_{model} \times 20}$ at each transformer layer. Integrate with HuggingFace PEFT.
Week 3	**Router Training**	Freeze the base model and A/B matrices. Train W_{router} on 100k OpenOrca/MetaMathQA sequences using next-token cross-entropy and load-balancing loss. Utilize bfloat16 and batch size 64 on the RTX 5090.
Week 4	**Evaluation & Ablation**	Execute MATH500, MMLU, and BBH benchmarks. Perform ablations (Token vs. Prompt routing, Dense vs. DARE B matrices). Format results and draft the arXiv manuscript.

Codebase Structure Modifications

- **Discard:** The EmbeddingRouter, GatedRouter, and the three-signal heuristics must be entirely deleted. They are conceptually obsolete.
- **Modify:** The RoutedLoRALinear must be rebuilt as TokenLevelMoELoRALinear inheriting

from torch.nn.Module. It must intercept the hidden states h_l, pass them through W_{router} to obtain a softmax distribution, and multiply this distribution against the 20 sparse B_k matrices prior to the down-projection via the Shared-A matrix.

- **Leverage:** Utilize HuggingFace peft and transformers for the base Qwen2.5-1.5B model management. Utilize vLLM for the final inference benchmarking to measure true token throughput.[30]

Checkpoint Validation

At the end of Week 2, a critical validation checkpoint must be passed: observing the routing distribution during a dummy sequence generation. If the router outputs a static distribution (e.g., constantly selecting adapter 3 for every token), the architecture is suffering from router collapse. If this occurs, the pivot strategy is to immediately increase the weight of the $\mathcal{L}_{balance}$ penalty and reduce the learning rate. The system is only on track if the routing distribution visibly shifts token-by-token (e.g., selecting the LINGUISTICS expert for syntactic structure and the MATH expert for numbers).

The 30% Improvement Claim

To declare empirical success, the system must demonstrate a strict $\geq 30\%$ relative improvement on **MATH500**. If the baseline Qwen2.5-1.5B model achieves ~35% accuracy on MATH500 [34], the TOSR composition must achieve an absolute accuracy of $\geq 45.5\%$ (35×1.30). Furthermore, the system must completely reverse the Synapta Phase 1 failure, proving that multi-adapter composition does *not* degrade single-domain queries, achieving a $\Delta \geq 0.00$ on single-domain benchmarks.

Paper Contribution Framing (arXiv Submission)

"We introduce Token-Level Orthogonal Subspace Routing (TOSR), a parameter-efficient multi-adapter inference framework that replaces static prompt-level linear composition with dynamic, hidden-state-driven expert switching; operating within the strict memory constraints of consumer hardware, TOSR effectively eliminates parameter interference through inference-time DARE sparsification, yielding a 30% improvement in complex mathematical reasoning over prompt-level routing baselines."

15. Mapping Overlaps in Benchmarks through Perplexity in the Wild - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2509.23488v2
16. ReasonerRank: Redefining Language Model Evaluation with Ground-Truth-Free Ranking Frameworks - ACL Anthology, accessed on April 7, 2026, https://aclanthology.org/2025.findings-acl.700.pdf
17. Line Goes Up? Inherent Limitations of Benchmarks for Evaluating Large Language Models, accessed on April 7, 2026, https://arxiv.org/html/2502.14318v1
18. Evaluating the Effectiveness of LLM-Evaluators (aka LLM-as-Judge) - Eugene Yan, accessed on April 7, 2026, https://eugeneyan.com/writing/llm-evaluators/
19. Effective LoRA Adapter Routing using Task Representations - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2601.21795v1
20. LoraRetriever: Input-Aware LoRA Retrieval and Composition for Mixed Tasks in the Wild - ACL Anthology, accessed on April 7, 2026, https://aclanthology.org/2024.findings-acl.263.pdf

21. 1 Introduction - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2601.21795v2
22. Beyond Adapter Retrieval: Latent Geometry-Preserving Composition via Sparse Task Projection - AAAI Publications, accessed on April 7, 2026, https://ojs.aaai.org/index.php/AAAI/article/view/39400/43361
23. Preference-Aligned LoRA Merging: Preserving Subspace Coverage and Addressing Directional Anisotropy - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2603.26299v1
24. Benchmarking Nvidia RTX 5090 - Computer Vision Lab, accessed on April 7, 2026, https://nikolasent.github.io/hardware/deeplearning/benchmark/2025/02/17/RTX5090-Benchmark.html
25. Nvidia RTX 5090 Review: Specs, VRAM, Benchmarks, and AI Performance - Runpod, accessed on April 7, 2026, https://www.runpod.io/articles/guides/nvidia-rtx-5090
26. Brainstacks: Cross-Domain Cognitive Capabilities via Frozen MoE-LoRA Stacks for Continual LLM Learning - arXiv, accessed on April 7, 2026, https://arxiv.org/pdf/2604.01152
27. Less is More: Resource-Efficient Low-Rank Adaptation - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2512.00878v1
28. LESS IS MORE: RESOURCE-EFFICIENT LOW-RANK ADAPTATION - OpenReview, accessed on April 7, 2026, https://openreview.net/pdf/827a777686f64e44fbfdc3dc6da422dc5f5e6ebd.pdf
29. CL-LoRA: Continual Low-Rank Adaptation for Rehearsal-Free Class-Incremental Learning - CVF Open Access, accessed on April 7, 2026, https://openaccess.thecvf.com/content/CVPR2025/papers/He_CL-LoRA_Continual_Low-Rank_Adaptation_for_Rehearsal-Free_Class-Incremental_Learning_CVPR_2025_paper.pdf
30. Private LLM Inference on Consumer Blackwell GPUs: A Practical Guide for Cost-Effective Local Deployment in SMEs - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2601.09527
31. ICML Poster Compress then Serve: Serving Thousands of LoRA Adapters with Little Overhead, accessed on April 7, 2026, https://icml.cc/virtual/2025/poster/46530
32. ICML Poster Learning to Route LLMs with Confidence Tokens, accessed on April 7, 2026, https://icml.cc/virtual/2025/poster/45145
33. Large Language Model Evaluation in '26: 10+ Metrics & Methods - AIMultiple, accessed on April 7, 2026, https://aimultiple.com/large-language-model-evaluation
34. Base Models Know How to Reason, Thinking Models Learn When - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2510.07364v2
35. Benchmarking Reasoning Robustness in Large Language Models - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2503.04550v1
36. GRAD: Generative Retrieval-Aligned Demonstration Sampler for Efficient Few-Shot Reasoning - ACL Anthology, accessed on April 7, 2026, https://aclanthology.org/2025.findings-emnlp.1047.pdf

37. DR-LoRA: Dynamic Rank LoRA for Mixture-of-Experts Adaptation - arXiv, accessed on April 7, 2026, https://arxiv.org/html/2601.04823v1
38. L1RA: Dynamic Rank Assignment in LoRA Fine-Tuning - ACL Anthology, accessed on April 7, 2026, https://aclanthology.org/2025.icnlsp-1.35.pdf
